Abstract

Background: The superficial temporal artery (STA), a terminal branch of the external carotid artery, supplies multiple regions of the scalp and face. Knowledge of the STA is important for reconstructive and aesthetic procedures of the head and face.

Objectives: The aim of this study was to map the STA in relation to anatomical landmarks.

Methods: Computed tomographic head angiographies of 215 patients were included in this study; the final analysis comprised 419 STAs. The STA’s main branches and variants were identified. The diameters of the STA and its frontal and occipital branches were measured, and the distance between the STA tree and anatomical landmarks was delineated.

Results: Frontal and parietal branches were recorded in 98.1% and 90.7% of patients, respectively. The mean diameters, measured 1 and 7 cm from the STA bifurcation for the frontal branch, were 0.97 ± 0.32 and 0.81 ± 0.26 mm, respectively, and for the parietal branch, the diameters were 0.96 ± 0.28 and 0.76 ± 0.23 mm, respectively. The STA bifurcation point was located above the zygomatic arch (ZA) in 75.6%, below in 14.7%, and on the ZA in 9.7% of patients. The mean distance from the ZA center to the STA bifurcation was 16.8 ± 16.0 mm.

Conclusion: The STA artery and its main branches follow a conservative course, and serious anatomical variations are relatively rare. The STA and its main branches may be localized using simple anatomical landmarks. An anatomical map showing artery-free zones in the lateral forehead region was presented, which may prove useful for plastic, reconstructive, and aesthetic surgeons.

Level of Evidence: 4

Editorial Decision date: October 15, 2018; online publish-ahead-of-print October 23, 2018.
The superficial temporalis artery (STA), a terminal branch of the external carotid artery, arises in the parotid gland behind the neck of the mandible. It is divided into 2 main branches, the frontal and parietal. The artery supplies the skin and muscles located on the scalp and lateral side of the face, the parotid gland, and the temporomandibular joint.\textsuperscript{1,2} In addition to the branches that mainly concern plastic surgery, the STA also branches into the transverse facial, auricular, zygomatico-orbital, and middle temporal arteries. Detailed knowledge of the anatomy of this region is essential for undertaking reconstructive and aesthetic procedures.

The temporal region borders the lateral part of the forehead, and these regions are supplied by the frontal branch of the STA. This region is of great aesthetic interest.\textsuperscript{3,4} Because of its location neighboring the eyes, and because it often shows early signs of aging, it is one of the most common locations for dermal filler injections.\textsuperscript{5,6} Proper injection technique and knowledge of the anatomy of this region, especially the location of the frontal branch of the STA, is crucial to avoid complications during injection, which include inflammatory nodules, tissue necrosis, hypersensitivity reaction, blindness, and cerebral ischemia.\textsuperscript{7,9} Recent studies have emphasized the facial danger zones, and how to minimize the complications related to filler use.\textsuperscript{10-12}

Another important clinical aspect of the STA supply is in reconstructive procedures that involve the temporoparietal, parieto-occipital, or the forehead and preauricular flaps.\textsuperscript{13-18} These flaps are used to cover various head defects, including baldness and external ear reconstruction. Proper planning of reconstructive surgery is a basic step in obtaining a satisfactory effect, and is linked with achieving an appropriate blood supply to the flap. Thus, detailed knowledge of the location of the STA and its branches is important for such procedures. Computed tomographic angiography (CTA) is the first choice for preoperative imaging in facial reconstructive surgery, because its imaging of small vessels is superior to that of magnetic resonance angiography.\textsuperscript{19}

A comprehensive knowledge of STA anatomy is crucial for avoiding serious complications and improving results. Thus, the aim of the present study was to present anatomical variations of the STA and develop a clinically useful map of the STA in relation to anatomical landmarks.

**METHODS**

The methods and protocols were performed in accordance with accepted guidelines. This study was approved by the Bioethical Committee of the Jagiellonian University, Krakow, Poland (no. 1072.6120.213.2017).

**Study Group**

Evaluation of STA anatomy in this retrospective cross-sectional study was conducted on patients who underwent a head CTA at the Department of Radiology, Department of Rescue Medicine and Multiorgan Trauma, University Hospital, Krakow, Poland between October 2017 and January 2018. Exclusion criteria were as follows: head trauma affecting the course of the artery, significant imaging artifacts (such as low quality or illegible images), history of craniectomy or craniotomy, and incomplete cross-sections. Of the initial 238 CTA patients available, 24 were excluded because of an insufficient field of view (n = 7), weak enhancement of the carotid artery (n = 6), repeated studies for 1 patient (n = 1), and missing data (n = 3). The remaining 215 patients were included in this study; 126 were females (58.6%) and 89 were males (41.4%). A total of 204 patients had their STA visualized bilaterally and 11 unilaterally, which provided a total of 419 STAs in the final analysis (right, 208; left, 211).

**Computed Tomographic Angiography Method and Image Evaluation**

The study was performed using a multi-row computed tomography scanner (GE Optima CT 660; GE Healthcare, Chicago, IL). The nonionic contrast agent iomeprol (70 mL administered; Iomeron 350; 350 mg iodine/mL; Bracco Imaging, Milan, Italy) was injected. After the bolus reached the common carotid artery at the level of C3-C4, the scanning procedure was started automatically. The imaged region ranged from the aortopulmonary window to the cranial vertex. The scanner settings were as follows: 120 kV, 200 mA, and 64 mm × 0.625 mm slice collimation. Axial 0.625-mm slices at increments of 1.25 mm were reconstructed using a 512 × 512 matrix, with a standard kernel applied.

The data were analyzed on a dedicated workstation (Advantage Workstation AW4.5; GE Healthcare, Chicago, IL) equipped with software for 3-dimensional volume-rendering postprocessing of images. All scans were reconstructed using a volume-rendering opacity setting of 45-300 Hounsfield unit and then investigated visually. The STA and its branches were included in the analysis, with data for both sides recorded separately. The features of the STA were evaluated by 4 radiologists who were experienced in head and neck evaluation.

**Measurements**

In each patient, the STA and its main branches were identified, and variants were noted. STA diameters were measured at the superior margin of the zygomatic arch (ZA), and
Koziej et al

1 cm before STA bifurcation. The diameters of the frontal and occipital branches were also noted 1 and 7 cm above the bifurcation. The bifurcation point was described in relation to the central point of the ZA (“+” above, and “−” below ZA). Two angles were also measured: (1) the angle between the frontal and parietal branches; and (2) the angle between the frontal branch and the ZA (Figure 1A). Moreover, 6 clinically important distances were delineated between the STA tree and anatomical landmarks, which are defined in Table 1 and marked in Figure 1A.

### Statistical Analysis

Qualitative features were presented as frequencies and percentages. Normal distribution was assessed using the Shapiro-Wilk test. A P value of < 0.05 was considered to be statistically significant. The homogeneity of variance was confirmed with Levene’s test. Quantitative features were characterized as mean ± standard deviation. Quantiles (Q1, median, Q3) were applied if a nonparametric test was performed to compare quantitative features in groups. To compare STA features between the left and right sides, a paired t test or the Wilcoxon rank test was used depending on whether data were normally distributed. Correlation coefficients were calculated to measure the statistical dependence between the parameters. The power analysis indicated that, to detect a simple correlation r (r = 0.2) using a 2-sided test, with a 5% significance level test (α = 0.05), and 80% power (β = 0.2), the minimum sample size was 193. Statistical analyses were performed using Statistica version 13.1 (StatSoft Inc., Tulsa, OK).

### RESULTS

The mean age of the included subjects was 53.9 ± 18.6 years (range, 18–92 years). The mean diameter of the STA measured 1 cm below the STA bifurcation was 1.6 ± 0.4 mm (range, 0.5–3.2 mm), and measured at the level of superior margin of the ZA, it was 1.3 ± 0.4 mm (measured for 331 STAs; range, 0.5–3.2 mm). There were no significant differences in the diameters between the left and right sides of the face (P > 0.05; Table 1).

Of the 419 visualized STAs, frontal branches were recorded in 411 patients (98.1%) and parietal branches in 380 sides/arteries (90.7%; Table 2, Figure 2A,B). The mean diameters measured 1 and 7 cm from the STA bifurcation were 0.97 ± 0.32 mm (range, 0.4–2.3 mm) and...
The distance between the center of the supraorbital margin and the frontal branch, measured vertically: 70.4 (57.9; 78.8) mm, 47.3 (84.0) mm.

The distance between the lateral angle of the orbital rim and the frontal branch, measured vertically: 36.6 (28.4; 45.7) mm, 23.0 (55.9) mm.

The distance from the point of the corpus of the zygomatic bone between the frontal and temporal processes to the frontal branch of the STA, measured vertically: 42.5 (33.2; 49.2) mm, 25.7 (54.9) mm.

The shortest distance from the point of the corpus of the zygomatic bone between the frontal and temporal processes to the point where the STA crossed the zygomatic arch: 37.2 (34.0; 40.4) mm, 31.4 (43.5) mm.

The distance between the external auditory pore to the parietal branch of the STA, measured vertically: 54.4 (44.2; 66.1) mm, 34.7 (74.5) mm.

The distance between the external auditory pore and the STA, measured horizontally: 8.9 (7.0; 10.9) mm, 5.6 (13.1) mm.

Table 1. Location and Features of the Superficial Temporal Artery (STA) with Reference to Facial Structures

No statistically significant differences were found between right and left sides ($P > 0.05$).

$0.81 \pm 0.26$ mm (range, 0.3–2.4 mm), respectively, for the frontal branch, and $0.96 \pm 0.28$ mm (range, 0.4–2.6 mm) and $0.76 \pm 0.23$ mm (range, 0.3–2.2 mm), respectively, for the parietal branch. Arteries with an inner diameter less than 1 mm (measured 1 cm from the STA bifurcation) were observed in 166 STAs (40.4%) for the frontal branch and in 136 STAs (35.8%) for the parietal branch.

The bifurcation point of the STA was located above the ZA in 282 STAs (75.6%), below the arch in 55 STAs (14.7%), and was projected onto the ZA in 36 STAs (9.7%; Figure 3). The mean distance from the center of the ZA to the STA bifurcation was 23.8 ± 11.4 mm (range, 2.6–65.3 mm) for a bifurcation located above the arch and $-8.1 \pm 4.4$ mm (range, $-23.4$ to $-2.3$ mm) for a bifurcation located below the ZA. The location of the bifurcation point is strongly correlated with the location of the frontal branch, but not with the parietal branch; for high-branching STAs, the frontal branch is located significantly higher in relation to the lateral angle of the orbital rim ($r = 0.44$, $P < 0.001$) and the zygomatic bone ($r = 0.48$, $P < 0.001$).

The angle between the frontal and parietal branches was $67.5 \pm 24.9$° (range, 5.0°–161.3°), and the angle between the frontal branch and the ZA was $43.2 \pm 12.2$° (range, 6.5°–110.8°). The angle between the frontal and parietal branches was strongly correlated with the location of the STA bifurcation point and was greater for high-branching arteries ($r = 0.69$, $P < 0.001$). An anastomosis between the parietal and frontal branches was noted in 15 STAs (3.6%) and the mean distance measured along the frontal branch from the STA bifurcation to the anastomosis point was $91.1 \pm 24.1$ mm (range, 52.3–132.3 mm; Figure 2C). In 3 cases, a double parietal branch was noted (Figure 2D), and in 2 patients, it branched off the occipital artery. In 16 patients, the parietal branch was hypotrophic or absent and its course was replaced by a hypertrophic posterior auricular artery (Figure 2E-F).
Table 1 and Figure 1 show the morphometric relationship between the STA tree and the facial anatomical landmarks. Using the 10th and 90th percentiles for distances between the anatomical landmarks and STA components, artery-free and arterial zones were delineated in the studied area of the face and scalp. In the preauricular area, the

**Figure 2.** Computed tomographic angiography 3-dimensional reconstructions showing variants of the superficial temporal artery tree: (A) absence of the frontal branch; (B) absence of the parietal branch; (C) anastomosis between the frontal and parietal branch; (D) doubled parietal branch; (E) parietal branch branches off the hypertrophic auricular posterior artery; and (F) absence of the parietal branch and hypertrophy of the auricular posterior artery.
safe zone, defined as an artery-free zone, is estimated to be only 5.6 mm wide, and the STA artery should be expected to be 5.6 to 13.1 mm from the external auditory pore (arterial zone; Figure 1B). The location of the STA parietal branch could be also estimated based on its relationship to the external auditory pore, but the zone where the parietal branch is located is much wider (39.8 mm) and extends from 34.7 to 74.5 mm above the pore (Figure 1B). The location of the parietal branch in this area does not depend on the location of the STA bifurcation point ($r = 0.12$, $P < 0.001$).

The frontal branch of the STA and skull bone structures form a triangle or trapezium in the area of the temporal hollow, and the zygomatic bone may be used as an orientation point (Figure 1B). The safe zone extends 25.7 mm above and 31.4 mm towards the ear from the zygomatic...
DISCUSSION

Several, mainly small, anatomical studies have described the STA.\textsuperscript{10,18,20-25} The current study presents the variations and morphometric features of the STA tree and delivers a morphological map delineating the area where the STA, together with its main branches, may be found in most patients.

There are several situations in which it is necessary to precisely locate arteries in the lateral forehead area, either to find and use the vessel or to avoid its injury. The STA’s adequate diameter, predictable location, and accessibility make this vessel ideal for free flap reconstruction of the midface and scalp.\textsuperscript{26,27} The STA and its branches are also important in reconstruction procedures that require creation of a temporalis flap. This flap is mainly used for reconstruction of maxilla, mandible, and oropharynx defects,\textsuperscript{14} as well as to create a temporoparietal fascia flap, which can be used in various procedures such as both cutaneous and mucosal oncologic defects; reconstruction of the auricle, skull base, and orbit; hair-bearing tissue transfer; and facial augmentation.\textsuperscript{28-30} The successful use of these flaps depends upon the anatomical features of the pedicles that contain frontal or parietal branches.\textsuperscript{18} Because of advances in microsurgery, free tissue transfer has become the preference for many surgeons in craniofacial reconstruction. Several other indications for temporalis flap use have been noted, including anophthalmia, unilateral maxillectomy defects, and facial reanimation in selected cases of facial nerve palsy.\textsuperscript{14} However, biopsy of the frontal STA branch is considered to be the gold standard method for investigating giant-cell arteritis, where there is a risk of iatrogenic injury of the temporal branch of the facial nerve.\textsuperscript{31} Thus, an appropriate anatomical approach to the biopsy is necessary to decrease the risk of complications.

The STA runs perpendicular to the tragus in the preauricular area, and should be expected in the area extending from 5.6 to 13.1 mm anterior to the external auditory pore (Table 1, Figure 1B). Other anatomical structures that may be found in this area are the temporal and zygomatic branches of the facial nerve, 1 or 2 accompanying veins, and the auriculotemporal nerve. The STA can be noninvasively located using light palpation or color duplex sonography examination at the preprocedural stage.\textsuperscript{32,33} However, when performing aesthetic procedures, imaging techniques may not be available and basic knowledge of the STA location is crucial. One of the general principles for safe filler injections is to “be aware of the pertinent anatomy outlined in the danger zones.”\textsuperscript{31} Even when a practitioner is unable to find a vessel in a particular patient, this basic anatomical knowledge can minimize potential risk of complications and help predict potential adverse events.

The current study confirmed that the STA bifurcation point is usually located above the ZA.\textsuperscript{18,25,34} There is a purely academic dispute as to which branch of the STA should be considered a direct extension of this artery. In our study, the frontal branch was observed to be a direct extension of the STA slightly more often than the parietal branch. However, no differences in these vessels’ dimensions were found in the current study, which is in contrast to previous anatomical studies that highlighted the dominance of the frontal branch.\textsuperscript{18} Therefore, based on our results, we conclude that both STA branches should be considered equivalent.

Our results show that the STA frontal branch is more uniform than the parietal branch in its origin, but its course is more variable. The frontal branch is rarely encountered below the ZA, and its position on the forehead is strongly correlated with the location of the STA bifurcation point. Within the temporal region, the frontal branch can be found on the bone point located between frontal and temporal processes of the zygomatic bone. The artery-free zone may be estimated as a section of a circle with a center in this point and a radius of 3 cm (Figure 1B). This would be a reasonable area to use for filler injection to minimize potential artery damage or occlusion. However, it is necessary to remember to stay above the temporoparietal fascia so as not to inject filler into the middle temporal vessels. To avoid direct injury to the frontal branch, Sheuer et al\textsuperscript{12} suggested performing soft-tissue filler injections of the temporal region from lateral to medial in the superficial subcutaneous plane just below the dermis to maximize safety. Because the course of the artery in this region above the artery-free zone is wide (3 cm), we advise that the needle should be in constant motion in this region to prevent accidental puncture.

Just above the supraorbital margin, the wide artery-free zone extends up to 47 mm above the eyebrow. Unfortunately, a recent study by Shin et al\textsuperscript{31} showed that this region overlaps with a neural danger zone, where the temporal branch of the facial nerve is located. However, although the courses of the artery and nerve are parallel, the nerve terminates earlier than the STA branch, and has a smaller diameter and a dispersed
fiber arrangement. This vicinity creates the possibility of mutual damage to structures, and may be clinically used to localize the temporal branch of the facial nerve during rhytidectomy. Lei et al.\(^\text{35}\) suggested in their study that a 5- to 6-cm temporal incision in the hairline made approximately 1 to 2 cm superior to the frontal branch is likely safe during rhytidectomy. The STA can be used to locate the temporal branch of the facial nerve. In the temporal region this nerve is situated inferior and anterior to the STA frontal branch. Shin et al.\(^\text{31}\) outlined 2 useful distances that can help locate the facial nerve. The first one is a horizontal line passing through the lateral canthus and the root of the helix, and the second is a parallel line passing through the supraorbital margin. The mean distances between the STA frontal branch and the temporal branch of the facial nerve are estimated to be 17.7 ± 7.3 and 23.2 ± 9.9 mm, respectively.\(^\text{31}\)

As much as 40% of the frontal and 36% of the parietal STA branches are almost negligibly small (<1 mm in diameter) and their damage during aesthetic procedures, especially injections, is unlikely. Our study also shows another important variant: the anastomosis between the parietal and frontal branches, which is present in 3.6% of patients. Such an anastomosis is located high on the skull and its presence should be considered when performing procedures in this region (Figure 2C).

Although this study is the largest to date on STA anatomy, it has several limitations. First, the STA tree is composed of smaller vessels that may not have been detected by CTA because this imaging method lacks sufficient resolution. Second, the depth at which arteries run (relative to the skin surface) was not assessed. Regarding the STA location within the temporal region tissue layers, previous studies have shown that above the ZA, the STA is located within the temporoparietal fascia (superficial temporal fascia). The major branches of the STA never reach the deep temporal fascia, although they supply the subdermal layer.\(^\text{36}\) Third, all the analyzed patients were Caucasian; thus, no interracial differences were investigated. Fourth, only the internal diameters of the arteries were measured, which is the result of the visualization tool used and may be explain why our diameters are smaller than those reported in cadaveric studies.\(^\text{18,25,37}\) Moreover, the anatomy of veins, which usually accompany arteries and are also important vessels in reconstructive and aesthetic medicine, was not evaluated in this study. Finally, the proposed anatomical map should not be used as a universal tool, because variations may occur in individual patients. Specifically, patients with craniofacial deformities were not included and the above results cannot be extrapolated to this group.

**CONCLUSIONS**

The STA and its main branches follow a conservative course, and significant anatomical variations are relatively rare. The frontal branch is negligibly small (<1 mm in diameter) in 40% of patients; the same is observed for the parietal branch in 36% of patients. The STA and its main branches may be located through the use of simple anatomical landmarks. An anatomical map showing artery-free zones, which may assist plastic, reconstructive, and aesthetic surgeons in planning procedures in the lateral forehead region, was presented.
